

Week 4

Description to Motion

Jaerock Kwon, PhD

Associate Professor

Electrical and Computer Engineering

University of Michigan-Dearborn

Today is dense, and that is deliberate

No class next Monday — 10/5, 개천절 대체공휴일.

You leave today with:

- **Lab 4** — URDF, TF, and a deliberately broken map
- **Lab 5** — Ackermann kinematics, self-study
- **The track preference form** — due Friday 10/9

Labs due **10/12**. Two-week window.

1. URDF and Xacro

Links and joints

- **Links** — rigid bodies: visual, collision, inertial
- **Joints** — fixed, revolute, continuous, prismatic

Written literally, a URDF is repetitive and unmaintainable.

Xacro adds properties, macros, and expressions — expanded before anything reads it.

```
xacro urdf/mitt.urdf.xacro > /tmp/mitt.urdf
```

MRider's URDF has no literal dimensions

Every value comes from `config/mitt_dimensions.yaml`.

Whose header reads:

NOTHING IN THIS FILE HAS BEEN MEASURED.

Every value is an ESTIMATE derived from the vendor's published dimensions.

Not an apology. A mechanism.

In November the Chassis track drops in measured numbers,
and no geometry anywhere else changes.

The trap being avoided

A predecessor's URDF carried:

- `chassis_mass = 300 kg` — for a ride-on car
- a controller config whose wheelbase **contradicted its own URDF**

Nobody noticed.

In simulation, nothing complains.

2. TF2

The tree, and who owns each edge

Transform	Published by	Kind
<code>map → odom</code>	<code>slam_toolbox</code>	dynamic — drift correction
<code>odom → base_link</code>	EKF	dynamic — local pose
<code>base_link → *</code>	<code>robot_state_publisher</code>	static, from the URDF

Ownership is exclusive, and enforced.

The Ackermann controller runs `enable_odom_tf: false`
so the EKF is the **sole** publisher of `odom → base_link`.

Two publishers for one transform

The robot jitters.

- Nothing errors
- Both publishers are behaving correctly
- The tree looks complete in `view_frames`

A fourth silent failure, and one you can cause yourself.

Two practical facts

`base_link` is at the rear axle centre, on the ground plane (REP-105).

That is why `base_link_height` and `wheel_radius` are both `0.09`.

Not a coincidence — a derivation.

`tf2_echo` needs `use_sim_time:=true`.

Without it you compare wall clock against sim clock and get extrapolation errors that look like a broken tree.

3. From description to motion

The chain

```
mitt.urdf.xacro
  | xacro expands
  ▼
/robot_description → robot_state_publisher → TF (base_link → *)
  |
  | ros_gz_sim create
  ▼
model spawned in Gazebo
  | <gazebo><plugin gz_ros2_control>
  ▼
controller_manager — loads → joint_state_broadcaster
    (inside the Gazebo process)   ackermann_steering_controller
```

Two load-bearing details

The controller manager runs **inside** the Gazebo process.

That is what `gz_ros2_control` does — and it is why the CycloneDDS problem is specifically about service **responses** crossing that boundary.

Actuation does not cross the ROS–Gazebo bridge.

Every entry in `gz_bridge.yaml` is `GZ_TO_ROS`: clock, scan, IMU, camera. Nothing in that file commands the vehicle.

The identical controller stack runs in simulation and on hardware, differing only in the `hardware_interface` plugin.

ADR-SW4. This is what the twin is **for**.

And that plugin does not exist

`mitt_controllers.yaml` is used **unchanged** in sim and on hardware.

Its header:

If a value here needs to be different on the real vehicle, that is a signal something is wrong with the model, not a reason to fork the file.

`mitt_hardware` — the real plugin — is **not written yet**.

It is the Software track's keystone. **Merge 3, Week 13, exists to prove it.**

4. Ackermann kinematics

The bicycle model

$$\tan \delta = \frac{L}{R} \quad R = \frac{L}{\tan \delta} \quad \omega = \frac{v \tan \delta}{L}$$

Two consequences you have already felt:

- $\mathbf{v} = \mathbf{0} \implies \boldsymbol{\omega} = \mathbf{0}$. A car cannot rotate in place
- Steering is bounded, **so the turning radius is bounded**

The number that shapes this course

$$R_{min} = \frac{L}{\tan \delta_{max}} = \frac{0.63}{\tan 22.5^\circ} = 1.52 \text{ m}$$

Appears **twice** in `nav2_params.yaml` —
`minimum_turning_radius` (planner) and `min_turning_radius` (controller).

And it is why `xy_goal_tolerance` is **0.6 m**, not 0.25 m.

A vehicle with a 1.52 m turning circle cannot make fine corrections near a goal.
Ask it to and it **orbits** — which is exactly what happened during bring-up.

5. Silent failure #3

The worst kind

Week	Failure	Symptom
1	<code>ROS_DOMAIN_ID</code> mismatch	Nothing visible at all
3	QoS incompatibility	Connection never forms
4	Wrong extrinsic	Everything runs, output quietly wrong

The LiDAR publishes. TF is complete. SLAM runs. The map is wrong.

Every component is healthy — and faithfully computing the consequences of one bad number.

What that gate is defending

MRider's mapping acceptance gate:

*Repeated observations of the same wall agree within **10 cm** over a **30 m** loop.*

Lab 4 has you introduce a **5 cm** error and watch it fail.

Now you know why the Chassis track measuring the real vehicle is not busywork.

Labs 4 and 5

Lab 4 — Describe the Robot

Add a rear camera to the URDF · verify TF · break an extrinsic by 5 cm · diagnose the map

Lab 5 — How Tightly Can It Turn?

Derive $R_{\min}$ · **predict before you measure** · find the clamp · explain a 2% gap

Both due 10/12.

The track preference form

Due **Friday 10/9**. Read Teams & Tracks first.

Track	For people who
Electrical & Firmware	like embedded work — or want to
Chassis & Measurement	like working with their hands
Simulation & Validation	like finding what everyone assumed was fine
Software & Autonomy	want the deepest ROS 2 work

Teams are **assigned**, announced 10/12. "No experience" is a fine answer.
